ABSTRACT

PID control is optimized here to control the course of a small autonomous robot for military applications. A Visual Basic program was written to model the robot response to the controller and provide a method of optimization. The computer model is based on empirical data gathered through testing. Controller theory, robot mechanics, and hardware implementation are all discussed as they relate to the ability of the robot to get from one location to another along an efficient path. The controller was tuned to provide optimal direction control and the model was evaluated for accuracy. The robot completed a 170 degree pivot turn in 4.0 seconds and a 170 degree differential turn in 5.1 seconds. The time predicted by the model for the each turn was within 10% of what the robot did.

ACKNOWLEDGMENTS

Thank you to LT John Herkamp for all the assistance in testing, fixing computer code, and explanations of how the hardware works. Thank you to Dawn Mikalatos for taking the time to read and edit this project. Finally, thank you to Professor Richard Harkins for support and explanations of different aspects of the project, sometimes over and over, and to Professor Peter Crooker for his assistance and feedback regarding the Visual Basic program.

THIS PAGE INTENTIONALLY LEFT BLANK

I. MOTIVATION AND PROGRESS OF AGV DEVELOPMENT

Robotic platforms can be useful for a variety of military applications. They provide a low-cost and safe way to carry out certain missions. Robots in general are useful for repetitive, monotonous, or data intensive operations. Currently both Unmanned Aerial Vehicles (UAV) and Unmanned Underwater Vehicles (UUV) are used in surveillance and intelligence gathering operations. Robotic ground platforms are currently being used in the Explosive Ordnance Disposal field (EOD) as operator controlled platforms. TALON is the most widely known, commonly used robot and has been utilized in Bosnia, Iraq, and at Ground Zero for a variety of missions including surveillance and bomb disposal. The development of an autonomous ground vehicle for intelligence gathering, observation, and explosive disposal has not yet been done.

The Naval Postgraduate School established the Small Robot Technology Initiative to develop small, low cost robots for military applications. A number of prototypes have been built incorporating commercial off the shelf (COTS) components to accomplish intelligence gathering and area monitoring without constant human interaction and control. Current development projects include a surf zone robot that could be launched from surface ships or submarines and gather intelligence about a beachhead, and another to autonomously clean FOD (foreign object debris) off flight decks and hangar bays. The most recent robot to complete anti- IED and surveillance missions is Maj. Ben Miller's AGV, shown in Figure 1. AGV incorporated infrared and sonar sensors for self directed collision avoidance, GPS guidance, 802.11 wireless communications, and a motion triggered camera to monitor an area for IED placement. LT John Herkamp's Bigfoot (Figure 2) is designed to disable IED's. Bigfoot includes the same obstacle avoidance software and sensors, but has a controllable arm to carry a counter charge. Although each platform has unique mission capabilities, many of the components and much of the control software is very similar and may only need to be modified slightly for each platform and new mission. The estimated cost of these small robots is around \$3,000; while the cost of the currently used Talon is \$60,000.

Figure 1. AGV

Each platform has a need for course control, even aerial and underwater platforms will need to be able to change and maintain course until they reach the desired destination. The ability to model how these platforms turn, and manipulate the type of locomotion each platform uses, is paramount to the robot being able to complete its mission. The modeling breaks down into two parts: (1) modeling how the platform responds to an input and (2) controlling that input to control course.

There are a number of different control methods that can accomplish this. Proportional, integral, derivative (PID) controllers are commonly used because they are simple to implement, flexible, can eliminate offset, and can avoid overshoot in slow responding systems or highly oscillatory systems (Riggs, 253).

AGV only uses proportional control to reach and maintain course while driving to new GPS waypoints sent by the controller. This has certain limitations, such as sustained error and the possibility of overshoot. Using only proportional control is inefficient and wastes battery power and time. Part of optimizing and improving Bigfoot over AGV is to

improve the robot's ability to drive itself from one point to another. Bigfoot has a complete PID control implemented and optimized. PID control eliminates error, eliminates overshoot and minimizes the time it takes to reach the new course, and can be used in either manual control or in autonomous mode. PID control is necessary to drive to new GPS waypoints, or complete a stationary turn to face a new direction.

Figure 2. Bigfoot

Part of the Bigfoot project was to develop a predictive model with the goal of solving for the optimal control coefficients. The theoretical model included parameters for the friction of the wheel-to-ground interface, the internal friction of the geared motors and the inertia of the motors and the robot platform. A good model would allow the robot to use different coefficients depending on the surface it was on, and therefore use optimized turns no matter where it was driving. In the end, an empirical model predicting how the robot responds to voltage differences across the wheels was used to

tune the controller. Bigfoot can now turn to a new course, without overshoot, in a minimum time and maintain that course until it reaches the desired location.

The model program was written in Visual Basic which provides an interface to test and evaluate different control coefficients. This thesis discusses the inputs, using the program, and how well the model predicts the operation of the real platform. The controller was tuned and the resulting turn data from the robot is presented alongside the prediction from the model.

II. CONTROL THEORY AND APPLICATION

A. CONTROL THEORY

Feedback controllers maintain control over a process by comparing the actual values of the controlled variables to the requested set-point and changing the manipulated variable. An everyday example of this would be driving a car at the speed limit. The requested set-point is the speed limit, the controlled variable is the speed of the car, and the manipulated variable is the amount of gas supplied to the engine, see Figure 3. All the controller operations are carried out by the driver.

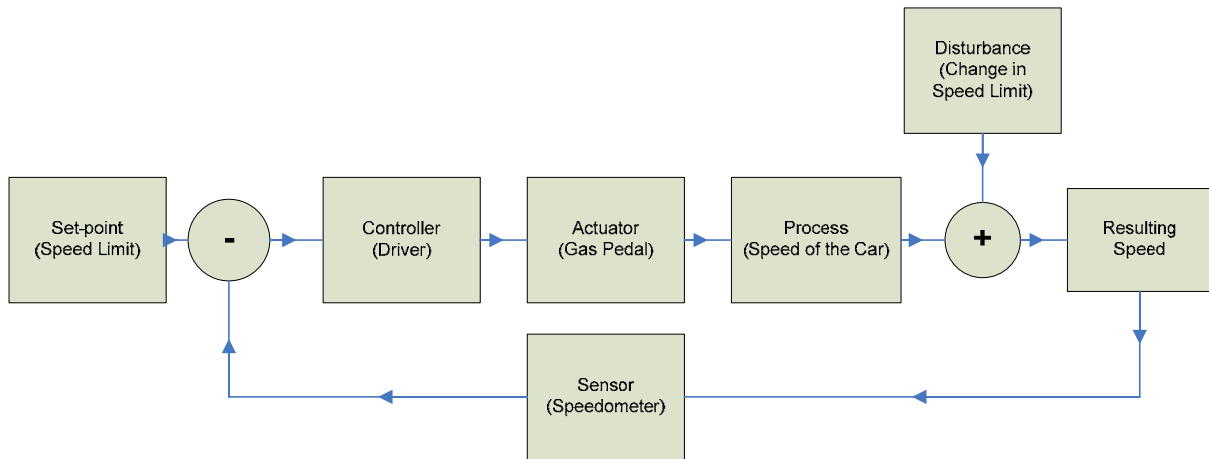

Figure 3. General controller diagram applied to the example of driving a car.

Digital or mechanical controllers can replace the operations carried out by the driver, in this example. There are numerous different types of controllers, but PID controllers are one of the most commonly used. PID controllers serve as a simple and flexible method of autonomously controlling a system, (Riggs, 213). Proportional control simply relates the set-point to the actuator by a constant. This is the simplest form of control, but in practice it often has a steady state error because it is a linear controller applied to a system that is almost always non-linear. The final error will depend on how close the change is to the controller's tuned set-point. Integral control minimizes the integral of the error over the time step of the system. If a steady state error exists, the integral of the error will build up over time and eventually influence the controlled

variable to eliminate the offset. The time step is the time it takes to go one time around the control loop (in Figure 3), and depends on the system. Derivative control impacts how fast the controlled variable changes. This can be used to limit the response from the controller so that the system does not continually overreact to changes or error. Each part of PID control can be used individually or in any combination, depending on the system. The full control equation including all three control types is shown in Equation 1. In Equation 1, $C(t)$ is the controlled variable and $e(t)$ is the error at time t . Changes to this value depend on the proportional coefficient, K_c , the integral coefficient, τ_i , and the derivative coefficient, τ_d . The coefficient of each term can be simplified so that $K_c = K_P$, $K_c / \tau_i = K_I$, and $K_c / \tau_d = K_D$. In the model and robot code these are the values set to optimize course control.

$$C(t) = C_o + K_c \left[e(t) + \frac{1}{\tau_i} \int_0^t e(t) dt + \tau_d \frac{de(t)}{dt} \right]$$

Equation 1. The complete time form of the control equation.

Different pieces of hardware must work together to get the robot to move in the correct direction. The control process as it applies to the robot is shown in Figure 4.

Figure 4. Control diagram relating the hardware to the process.

All control operations are carried out by a BL2000 microprocessor. The actuators on the robot are the motor drivers. These determine the direction and speed the motors turn. The process is the interaction between the four motors driving the robot, the mass of the robot and the surroundings. The sensor is an electromagnetic compass, which provides heading information to the processor.

The controlled variable can be treated as an oscillator, and will have three possible outcomes from tuning. The system can be under-damped, critically damped, or over-damped. Critical damping represents the fastest correction that can be made without having an overshoot. Figures 5, 6, and 7 show how the controlled variable approaches the setpoint for the three possible damping factors. These plots show how a simple oscillator responds to different damping factors. Damping can come from the controller or from the surroundings through friction. For the robot, the controlled variable is the voltage signal sent to the motor drivers. The error is the difference between the desired heading and the current heading.

Figure 5. An under damped system.

Figure 6. A critically damped system.

Figure 7. An over damped system.

B. TUNING CONTROLLERS

The purpose of tuning controllers is to minimize deviations from set-point, maintain the set point, avoid excessive variation of manipulated variables, and eliminate offset (Riggs, 253). Since it is impossible to completely satisfy all of the above criteria, a balance must be reached that is unique for the system and based on the required performance attributes. For example, systems that utilize valves to make set-point changes can be worn out quickly by both excessive change, and hitting the maximum open and closed positions often. The robot differs from this type of system in that changing the voltage to the motors often does not affect the life of the platform. Since some voltage signal is always being sent, properly controlling the course involves varying the existing signal. This system has a ± 5 degree uncertainty because of the compass, so a small offset is not a problem. However, a quick response is desired, and oscillations must be avoided to conserve battery power. Smarter driving means less time and energy spent getting to the destination, and more time and energy to do the mission once there.

If the controller is not optimized properly, the robot could have sustained oscillations or become unstable and the error will grow. The ultimate goal is to incorporate and tune a controller that corrects the course in a critically damped manner for all turns on all surfaces.

There are a number of different methods to tune controllers. Some methods are mathematical; others involve guidelines from the numerous applications of such controllers. It is also possible to empirically test until optimum values are found, although this can be tedious. While tuning the robot's controller, the initial values were based on general guidelines and then tuned with empirical testing both on the robot and the model. Tuning this way was possible only because the testing can be done very quickly with the software model. If new controller coefficients had to be tested using the robot it would take much longer and another method would be needed.

C. OTHER INDUSTRIAL APPLICATIONS

PID controllers are commonly used in industrial processes because of their flexibility, ease of use, and robustness. Cruise control on cars, vehicle suspension systems, tank level and temperature are some examples of places where PID control has been used. PID controllers can be mechanical in nature or software based in digital control systems. The first applications of PID control were through pneumatic controllers in chemical processing industries in the 1930's (Riggs, 213).

In certain circumstances, PID control does not provide a robust enough control mechanism, so model predictive control (MPC) is used instead of, or in addition to PID control. These circumstances are when there is a long time delay; major nonlinearities; large and frequent disturbances; multivariable interactions; or constraints on the system (Miller, 1). In large industrial plants there may be hundreds or thousands of control loops, many of which interact with each other. Modeling and efficient control is an economic necessity for these plants. The industrial application of PID control is not that different from applying the same concepts to the robot, only some different tools (types of control) are used and companies spend years developing both theoretical and empirical models of such plants.

THIS PAGE INTENTIONALLY LEFT BLANK

III. HARDWARE

Systemic error that exists will lead to some difference between the model and how the real robot performs. This is why the bearing predicted by the model does not exactly match what really occurs and why a ± 5 degree course is acceptable. The systemic error comes from the hardware that works to make the robot turn. For a more in-depth explanation of all the hardware, see John Herkamp's thesis, (Herkamp, 11-35).

A. PROCESSOR

The BL2000 microprocessor (Figure 8) runs a Dynamic C program code, modified for Bigfoot by John Herkamp (Herkamp, 36). The microprocessor operates at 22.1 MHz and calculates the desired course based on the coordinates sent by the operator and the GPS unit. In addition to controlling the motor speed, the processor takes in information from the sensors and communication router and carries out other operations. Obstacle avoidance, camera operation, thermal sensor, arm operations, and communication are all things the processor controls.

Figure 8. BL2000 microprocessor

B. MOTOR DRIVERS

The motor driver takes the voltage signal sent by the controller and converts it to a pulse width modulated signal. The motor driver is a 50 V, 20A H-bridge motor driver. The advantages of this type of motor driver are that none of the components have a continuous current stress and it can drive the motor forward or in reverse at varying speeds. Within an H-bridge circuit the resistances are varied so that different amounts of current flow through the motor in the desired direction, see Figure 9. In Figure 9, when the resistance through R_1 and R_3 is the lowest, the motor will run in one direction, but when the resistance R_4 and R_2 is the lowest the motor will turn in the opposite direction. Variable amounts of current are sent by controlling the resistance. In practice transistors replace the resistors to variably control the flow of current.

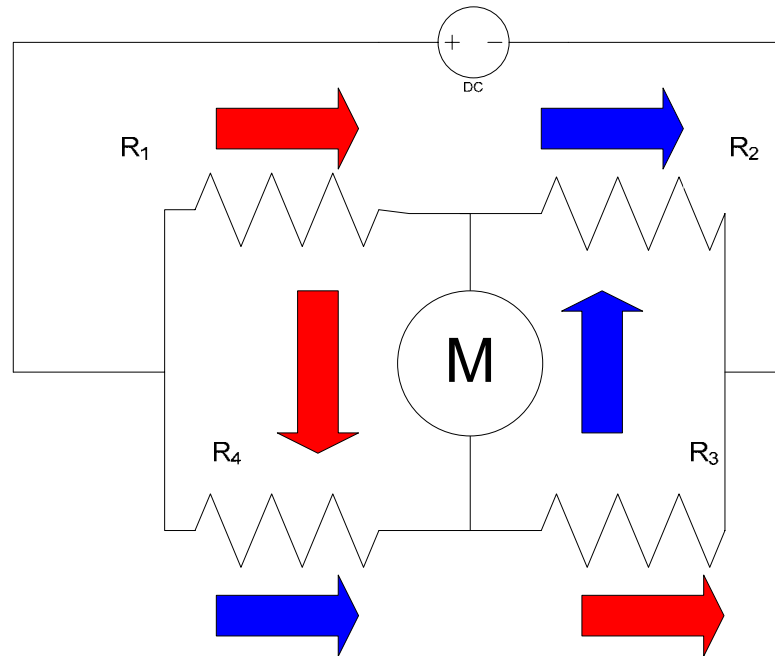

Figure 9. An H-bridge circuit diagram.

Figure 10. H-Bridge motor driver (From Superdroid Robots).

C. MOTORS

The motors are powered by a 24 V nickel-metal hydride battery. An independent battery powers all the electronics on board. The motors (Figure 11) have a loaded turn speed of 190 rpm, a torque of 0.5 N-M, and operate at a current up to 900mA. The motors can drive the robot, which has a mass of 11.8 kg, at about 3.8 MPH, which is a fast walking pace. With the batteries on board the motors can drive for about 2 hours, depending on conditions and use.

Figure 11. Drive motor (From Superdroid Robots).

D. ELECTRONIC MAGNETIC COMPASS

Once all these parts work together the robot drives along a new course. The sensor that measures that course is an electronic magnetic compass, shown in Figure 12.

Figure 12. Electronic magnetic compass (From Superdroid Robots).

The compass uses a magnetoresistive sensor. Resistance of certain magnetic materials will change under the influence of an external magnetic field. In this case the external field is that of the Earth. Figure 13 shows a diagram of how the magnetic field and resistance are related. H represents the magnetic field of the earth and will influence the magnetization of the plate. The resistance in the permalloy varies according to Equation 2.

Figure 13. Magneto resistive effect.

$$R = R_o + \Delta R_o \cos^2 \alpha$$

Equation 2. Resistance in the permalloy.

Four of these plates are arranged in a Wheatstone bridge configuration. Each rectangle represents one of the plates shown in Figure 14. The voltage drop across $+V_o$ to $-V_o$ is the signal that provides the measure of heading. The voltage across V_{cc} to GND is the applied voltage from the power source.

Figure 14. Bridge configuration for magneto resistive effect. (Philips Semiconductors)

To account for other magnetic fields present due to the robot's electronics, the compass was calibrated manually by aligning to magnetic north. Once the calibration was complete, the compass aligned magnetic north along the same direction as the other compass, and showed the correct heading for the cardinal directions. Without calibration, the compass does not even read 90 degrees between the cardinal directions properly. The compass sends out an 8 bit signal, and therefore has 256 possible values. Dividing 360 degrees by 256 possible outputs means the compass is precise to 1.4 degrees, as it is implemented here. It is possible to get the compass to operate at ± 0.1 degrees with a pulse width modulated signal, but that involves significant software modifications and would not be very helpful since the GPS is only accurate to commercial specifications.

For a complete description of all the hardware capabilities and how the hardware was incorporated into the robot see Herkamp, pages 11 to 35.

THIS PAGE INTENTIONALLY LEFT BLANK

IV. DEVELOPMENT OF THE MODELING EQUATIONS

A. BASIC CONCEPTS

When the robot moves, the motion can be a combination of both forward translational movement and rotational movement. There are two options for making course corrections, stopping to turn or turning while driving. The first is a *pivot turn* and the robot drives in a straight line until it reaches the waypoint, or until enough error is built up, then stops and turns using reverse motion one side and forward motion on the other side. This type of turn is faster, but the overall process is much slower and puts unnecessary wear on both the motor controllers and wheels, because they are switching directions often. The other option, a *differential turn*, is to slow one side down while continuing forward motion. Figure 15 shows the two types of turns. Each type of turn can be useful, depending on the circumstances. For instance turning the robot in place to look at something or turning in tight spaces requires a pivot turn, but when making small adjustments while driving to a new destination it is more efficient to use a differential turn.

Figure 15. Types of turns: (A) differential and (B) pivot.

B. PRELIMINARY THEORETICAL MODEL

The original goal was to develop a widely applicable model of the how robots turn that depended only on inertia and friction, and from which the optimal control coefficients could be solved for. The basic idea was to start with the equation of motion for the motors (modeled as one motor) and work through the influence of friction and inertia and the control coefficients to a final equation of motion for the platform; resulting in the equation of motion for the optimized turn of the robot, based on proportional and derivative control coefficients, inertia, and friction.

Equations 3 through 9 show the development of the theoretical model. Equation 3 is the equation of motion for the motor and can be equated to the torque from the controller. T_m is the torque of the motors, J in the inertia term, and F is the friction term. θ represents the course heading.

$$T_M = J\ddot{\theta} + F\dot{\theta}$$

Equation 3. Equation of motion for the motors.

$$T_M = K_e(\theta_0 - \theta) - K_d\dot{\theta}$$

Equation 4. Torque due to the controller.

In Equation 3, K_e is the combination of the proportional relationship between the voltage to the motor and the proportional relationship between the heading error that exists and the current to the motor. K_d is the derivative feedback coefficient. By equating these two relationships is it possible to solve for solutions in terms of θ .

$$-K_e\theta - K_d\dot{\theta} = J\ddot{\theta} + F\dot{\theta}$$

$$\text{set } \theta_0 = 0$$

$$J\ddot{\theta} + (F + K_d)\dot{\theta} + K_e\theta = 0$$

Equation 5. Combined equation.

$$\theta = \theta_0 e^{q \cdot t}$$

Equation 6. Proposed solution.

By taking the first and second derivative of Equation 6 and substituting into Equation 5, the quadratic Equation 7 is the result, and the standard quadratic equation can be used to find solutions.

$$q^2 + \left[\frac{F + K_d}{J} \right] q + \frac{K_e}{J} = 0$$

Equation 7. Quadratic equation of proposed solution.

$$q = -\left[\frac{F + K_d}{2J} \right] \pm \frac{1}{2} \sqrt{\left[\frac{F + K_d}{J} \right]^2 - \frac{4K_e}{J}}$$

Equation 8. Solutions for q using the quadratic equation.

The solution for θ is shown in Equation 9. When $\omega = 0$ then system will be critically damped.

$$\theta = \theta_o e^{(-\frac{1}{2}\alpha t)} e^{(-\frac{1}{2}\omega t)}$$

$$\alpha = \left(\frac{F + K_d}{2J} \right) \quad \omega = \sqrt{\left(\frac{F + K_d}{J} \right)^2 - \frac{4K_e}{J}}$$

Equation 9. Solution for θ .

Two problems existed with this approach; one is that it did not accurately predict what the robot really did and the second being that it could only model a pivot turn. The prediction was not accurate because the turn rate predicted by the Equation 9 was much greater than the maximum turn of the robot. The turn rate is the slope of the turn line shown in Figure 16. A pivot-turn has limited application since it is only part of how the robot turns, and is used less often than the differential turn. Figure 16 shows how the theoretical model matched the real data.

Figure 16. The theoretical model versus real data.

One reason the theory did not work was that it turned at twice the maximum turn rate of the robot. By looking at the steepness of the curve in Figure 16, it can be seen that the model predicted a turn rate that was much faster than the maximum turn rate the robot was capable of. Because of this, the time the model said it would take to complete a turn was half of the actual time and did not provide a way to optimize coefficients, because the proportional and derivative control coefficients were solved for, not chosen based on response. The coefficients required to make $\omega = 0$ (in Equation 9), were not the optimal coefficients. When other coefficients were used, both in the robot and in the model, values could easily be found that were better; most likely because the influence of inertia (J) and friction (F) were not considered correctly. Since the theoretical model did not give a good way to control the robot an empirical model was developed to optimize the controller.

In addition to the motors, there are two main influences on the direction of the robot. The first is friction, which depends on what surface the robot is traveling on. The second is inertia, including rotational inertia. During a differential turn there is a transition from forward motion to rotation. The robot has static friction coefficients approaching one for most surfaces. The wheels are made of rubber, which has a higher friction coefficient than most materials. Friction helps the wheels get traction to move, so

although too much friction can hinder a fast turn, it is necessary for the robot to drive. During testing on cement, the coefficient of static friction was .96. This value was found by pulling on the robot with a spring scale until it started moving then dividing that value by the weight of the robot. Static friction is usually the main friction influence since the wheels are usually turning. When the robot does a pivot turn however, the inside wheels tend to drag, so kinetic friction contributes during a pivot turn.

C. DEVELOPMENT OF THE MODELING EQUATIONS

Two separate tests were done on the robot to develop empirical equations that predict how the robot would respond to applied voltage signals to the wheels. The first test was for a pivot-turn, where the wheels on one side were set to a range of forward voltages while the other was set to the equivalent reverse voltage. Testing included both clockwise and counterclockwise turns. The turn was completed for a set time and the total direction change was converted to a turn rate at that voltage. Table 1 shows the turn rate for each voltage. By applying a linear best fit line to the data, an equation was developed to predict how many degrees the robot will turn for a given voltage signal.

| Voltage Difference (V) | Turn Rate (deg/sec) | |
|------------------------|---------------------|------|
| | Right | Left |
| 3.0 | 84.0 | 91.0 |
| 2.8 | 71.0 | 79.0 |
| 2.6 | 57.0 | 67.0 |
| 2.4 | 49.0 | 50.0 |
| 2.2 | 32.0 | 33.0 |
| 2.0 | 16.5 | 22.5 |
| 1.8 | 6.0 | 6.0 |
| 1.6 | 1.0 | 0.0 |

Table 1. Turning rates for a pivot turn.

In the second test, the differential turn rate was measured. To test this, one side was slowed down by a small incremental amount for a set time period, while the other side moved forward at the normal driving speed. The turn rate was measured and another equation was developed based on the data. Table 2 shows the turn rate for each measured voltage for a differential turn. This test was also completed for clockwise and counterclockwise turns.

| <u>Voltage Diff.(V)</u> | <u>Turn Rate(deg/sec)</u> |
|-------------------------|---------------------------|
| 2.5 | 71.2 |
| 2.3 | 64.3 |
| 1.5 | 18.2 |
| 1.4 | 17.4 |
| 1.3 | 14.6 |
| 1.2 | 14.0 |
| 1.1 | 12.2 |
| 1.0 | 11.1 |
| 0.9 | 10.9 |
| 0.8 | 9.8 |
| 0.7 | 7.6 |
| 0.6 | 6.8 |
| 0.5 | 5.9 |
| 0.4 | 4.8 |
| 0.3 | 3.6 |
| 0.2 | 2.0 |

Table 2. Turning rates for a differential turn.

Based on the data from these tests, two equations were developed; Equation 10 for a pivot turn and Equation 11 for a differential turn. Figures 17 and 18 show how these equations relate to data collected. The pivot turn has two curves because the robot veers when driving straight. The robot veers due to slight voltage differences and misalignment of the motor mounts. The misalignment pushes it when turning left and slows it when turning right. No difference in turn rate depending on the direction was noticed for a differential turn, probably because the misalignment is not significant enough to influence the slower turn. The error bars represent +/- 1.4 degrees, the accuracy of the electronic compass.

Figure 17. Pivot turn rate versus voltage difference.

$$T_{Right} (^{\circ} / \text{sec}) = 62.2 \cdot (\Delta V) - 103$$

$$T_{Left} (^{\circ} / \text{sec}) = 68.6 \cdot (\Delta V) - 114$$

Equation 10. Model equation for a pivot turn.

Figure 18. Differential turn rate versus voltage difference.

$$T(^{\circ}/\text{sec}) = 12.00 \cdot (\Delta V) - 0.28$$

Equation 11. Model equation for a differential turn.

When the robot first starts turning it has to overcome inertia and friction. This was modeled in the software by limiting how fast the model could “turn” in the first three time steps. For a pivot turn the initial turn rate was limited to 2 degrees per time step for the first three time steps and was based on experimental turn data. For a differential turn the limit was set to 4 degrees for the first three time steps, which was also observed during testing.

There is a range of voltages in which the robot does not have enough power to get going or stay going. To start moving, the motors must overcome static friction and inertia, and to keep the robot moving there must be enough power to overcome kinetic friction. The minimum voltage needed to get the robot going is the static stall voltage, and will be greater than the voltage required to turn the motor when no load is applied. The voltage required to keep the robot moving is the kinetic stall voltage. To determine what these were, incrementally lower voltages were sent to the motors until the robot could not keep moving, or in the static case could not start moving. The stall voltage was modeled by setting the course change to zero when the controller calls a voltage below the stall voltage. Stalling occurred primarily during pivot turns. Integral control becomes the only factor that influences the voltage when the stall voltage is reached, because the integral of error will have to build up before any change will be called that is above the stall voltage. Table 3 shows the stall voltages.

Stall Voltages:

| | Static | Kinetic |
|---------|--------|---------|
| Forward | 2.3 | 2.4 |
| Reverse | 2.8 | 2.6 |

Table 3. Stall voltages.

Equations 10 and 11 and the information from Table 3 are applied to the third step (Robot or Model) in the Robot Control loop as displayed in Figure 19 below. The adjusted motor control voltages are the entering argument for this step and the development if this parameter is discussed next.

D. COURSE CONTROL

The model we develop here provides an empirical prediction of how the robot turns based on adjusted motor control voltages as a function of heading error. The model also provides a method of optimizing PID steering control coefficients for our platform. It could be applied to other platforms with similar physical characteristics. These characteristics would include any two or four-wheeled robot with a motor controller for each side, including robots with a tank tread. Three-wheeled robots or any other omni-directional platform would require some code modifications.

Figure 19 shows a diagram of how initial course information is converted into a usable voltage signal to the motors. The desired heading, calculated by the processor, is compared to the current heading, measured by the sensor. The result gives an error, a number, between the actual and desired heading. The error is transformed to a dimensionless scaled voltage signal according to the equations derived from Figure 20. That scaled voltage signal is then adjusted by a PID control transform in order to avoid overshoot and offset. The adjusted voltage signal then goes to the motor drivers, which sets the actual voltage (not dimensionless) to the motors. The motors turn, and the robot comes to a new heading. Then the whole process starts over.

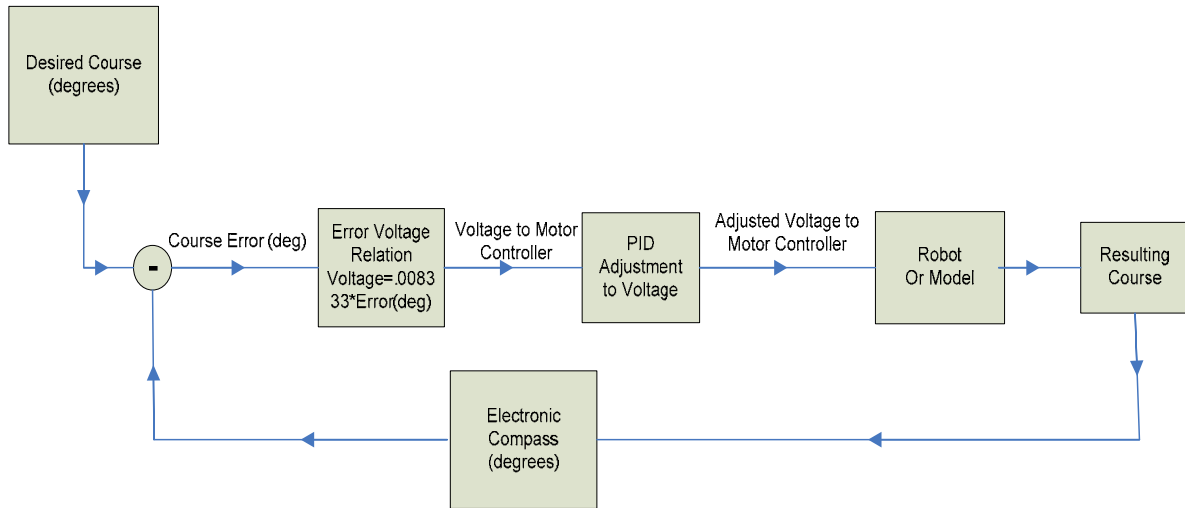

Figure 19. Robot Control Schematic

1. Turning Voltage

Figure 20 shows how heading error is converted to the scaled voltage signal for the left and right motors. The vertical axis represents the range of voltages from the BL2000 to the motor controller. The horizontal axis is the calculated error, and is the difference between the desired and actual heading of the robot. We define the 2.5-volt intercept for the left and right motor as the stop voltage. On the figure, voltage values between 1 and 2.5 volts indicate a reverse direction for the applicable motor, while voltage values that fall between 2.5 and 4 volts would specify a forward direction. For example, a 60-degree positive bearing error would indicate a 2-volt signal to the right motor and a 3-volt signal to the left. Since 2-volts falls between 1 and 2.5 the right motor would turn at a medium speed in the reverse direction. Similarly, the 3-volt signal falls between 2.5 and 4 and would specify a medium forward speed for the left motor. Consequently the robot would make a pivot-turn to the right at medium speed.

Figure 20. Error to Motor Control Voltage Conversion

The equations of the lines for Figure 20 are shown in Equation 12. Pink is the voltage to the right motor, blue is the voltage to the left motor, when the error is the desired course minus the current course, as it is in the code. They are used in the Visual Basic algorithm, to calculate the applicable voltages based on error. The slope of the voltage-error line ($m_{\text{voltage slope}}$) is the total range of voltage, $V_{\text{max}} - V_{\text{min}}$, (1.5 V) divided by the total possible error (180°). The intercept must be the stop voltage (2.5 V) so that when no error exists the robot will stop turning. V_{right} and V_{left} are the voltages needed to do a pivot turn to eliminate the error E° .

$$m_{\text{voltage slope}} = \frac{V_{\text{max}} - V_{\text{min}}}{E_{\text{max}} - E_{\text{min}}} = \frac{1.5}{180}$$

$$V_{\text{right}} = 2.5 - .00833 \cdot (E^\circ)$$

$$V_{\text{left}} = 2.5 + .00833 \cdot (E^\circ)$$

Equation 12. Equation of the lines.

2. PID Adjustment to Voltage

The next step in our control loop is to apply the PID transform, a code version of Equation 1, to the scaled voltage signal just calculated.

Since the PID control used here scales the actual voltage signal based on Figure 20, the K_P and K_I and K_D control coefficients are all unit-less. The actual control equation, which includes the PID coefficients, programmed into both the robot software and the model software is shown in Equation 13. P_{scale} , i_{scale} and d_{scale} are the equivalent of error from Equation 1, in terms of voltage. The $E_{\text{old}}^\circ - E_{\text{new}}^\circ$ represents the change in heading during one loop through the process.

$$\begin{aligned}
V_{inside} &= 2.5 + (K_P \cdot p_{scale} + K_I \cdot i_{scale} + K_D \cdot d_{scale}) \\
p_{scale} &= (E^\circ \cdot 0.00833) \\
i_{scale} &= p_{scale} + i_{scale} \\
d_{scale} &= ((E^\circ_{old} - E^\circ_{new}) \cdot 0.00833) \\
.00833 &= \frac{1.5}{180} \text{ (converts } E^\circ \text{ to volts)} \\
E^\circ &= \text{error in degrees}
\end{aligned}$$

Equation 13. Control equation used in the robot and the model.

The control equation calculates the voltage to the inside wheels. The voltage set for the outside wheels depends on the type of turn being completed. For a pivot turn the outside voltage was set to five minus the inside voltage, and for a differential turn the outside voltage is set to one, the full forward speed.

3. Systemic Error

Certain limitations arise from the components and reality of the system. Some of these can be adequately transferred into the model; however some simply contribute to error between the model and the robot. If the error between the model and the real system is small enough, then the model can be used to predict the response of the real system to the tuning coefficients and the controller can be optimized easily.

One of the limitations is a dead band limitation in the motor controllers. At 2.5 V $\pm 2.5\%$ the motor will stop. Using this information the minimum error can be calculated. This is simulated within the model by setting the maximum error in the code. Equation 14 shows how the maximum accuracy of the motor controllers is calculated. The maximum error in the model and in the software to run the robot was set to 5°.

$$D_b = 2.7\%$$

$$D_b \cdot V_{range} = V_{accuracy}$$

$$\pm .027 \cdot 2.5 \cdot \frac{1}{2} = \pm .034$$

$$e^\circ = \frac{V_{accuracy}}{m_{voltage\ slope}}$$

$$.034 \geq .00833 \cdot e^\circ$$

$$e^\circ = \frac{.034}{.00833} = 4.1^\circ$$

Equation 14. Error due to dead band.

In Equation 14 the voltage dead band (D_b) is 2.7% for the motor controllers, from the manufacturer specifications. The possible voltage range is 2.5 V, so the voltage dead band on either side of the stop voltage (2.5 V) is .034. Using the slope from the voltage-error equation ($m_{voltage\ slope}$) (Figure 20) this can be converted to how many degrees the motor controllers will be accurate to (e°).

In addition to the stop voltage dead band, there is also a stall voltage limitation. The stall voltage is defined as the applied motor voltage required too overcome robot friction and inertia. Table 3 shows the stall voltages, and a discussion of how they were modeled is addressed in the modeling equation section. The robot also veers left at a rate of about 1degree per 5 yards, which influences pivot turns, but not differential turns.

Another limitation is that the electronic compass has only 256 possible values. So instead of representing a circle with 360 degrees, the compass can only choose one of 256 values, therefore each compass value corresponds to about 1.4° . After the conversion, the heading is an integer value, whereas the course calculated from the GPS data is continuous to three digits.

E. PROGRAM DEVELOPMENT

1. Program Inputs

The modeling program developed provides an easy and quick way to test control coefficients for the robot, and could easily be applied to other platforms with some small

modifications in code. The user enters into the program an initial heading, a desired heading, and the PID coefficients to be tested. Figure 21 shows a screen shot of the program. The program for the differential turn looks the same, except for different titles and a different picture showing the type of turn that is being modeled.

Figure 21. Modeling program interface.

All the input boxes (shown in Figure 22) are open, and all need a value. Output values are not in a box. If one type of control is not going to be used, a zero is entered in the space for the coefficient.

The input fields are as follows:

- Time Elapsed for Turn (ms):** 5100
- Initial Heading (deg):** 172
- Desired Heading (deg):** 5
- Current Heading (deg):** 2.0
- Current Error (deg):** .0
- Proportional (Unitless):** 1.5
- Integral (Unitless):** 0
- Derivative (Unitless):** 3.5

Figure 22. Modeling software inputs

Controlling the program is user friendly and done using the command buttons shown in Figure 23. The “Go!” command is used to start the program once all the inputs have been entered. The “Export” button copies the data plotted in the charts the to computer clipboard so it can be pasted into another application (i.e. Excel) allowing the model to be compared to real data. The “Quit” button ends the program.

Figure 23. Program commands.

The proportional and derivative control coefficients were chosen to critically damp the system. Some general rules exist to establish a starting point when choosing control coefficients (Cabezas, 15). These are:

- Set the integral gain to zero
- Set the proportional gain to a reasonable starting value (KP)
- Set the derivative gain (KD) to twice the KP

Following these guidelines, the initial values for KP and KD were chosen to be 1 and 2, respectively and later adjusted. This uses the initial voltage calculation that is only based on error, but with a limit on how much voltage change can be made.

The iterative process of setting the voltage, calculating the response, and setting another voltage is within a “while” loop, in the Visual Basic code. The model calculates current error and updates the animation, table, and charts for the current heading. Then a new voltage is calculated based on the error and the control coefficients and the predicted response determines the new heading. Then the whole process the repeats. For the exact modeling code, see Appendix 1 and 2.

The Visual Basic language was chosen so that the end product can easily be used by a person with little knowledge of computer programming. If the theoretical model had been used instead of the empirical model, the user would only need to know the inertia and friction of the platform to be able to optimize the controller. The empirical model is more user friendly than a MATLAB or C program, where the user would have to be very familiar with that language/ software to use the model. Visual Basic provides a way to view the information and export the data as well as any of these other software options. The disadvantage of Visual Basic, at least with the version used here, is that it does not handle imaginary numbers easily. This may have been a contributing factor in why the theoretical model did not fit the real data well.

2. Program Outputs

There are three ways of interpreting the calculations completed within the model: an animation, a table, and two charts. The animation, Figure 24, shows a visual simulation of how the robot will turn. The blue line represents the front of the robot, and will be pointed in the direction the robot is driving. The top of the page represents 0/360 degrees or due north, just like the top of a map represents north.

Figure 24. Model animation.

The table shows the current heading and desired heading for each time step. The robot takes approximately 340 ms to cycle through the reading of the compass, calculations, data output, and output of new voltages to the motors, therefore the model calculates the heading at the same 340 ms interval. Figure 25 shows the data table from the modeling software.

| Time (ms) | Current Heading (deg) | Setpoint (deg) ▲ |
|-----------|-----------------------|------------------|
| 0 | 172.0 | 5 |
| 340 | 168.0 | 5 |
| 680 | 164.0 | 5 |
| 1020 | 146.0 | 5 |
| 1360 | 128.0 | 5 |
| 1700 | 110.0 | 5 |
| 2040 | 92.0 | 5 |
| 2380 | 74.0 | 5 |

Figure 25. Model data table.

Along the right side of the program window there are two charts. The charts show the actual heading and the heading error. The heading error chart has proven to be the most useful since it is not subject to jump across 0 to 360.

Figure 26. Chart output from the modeling program.

For a workable configuration of inputs, the error should approach zero. Error will always be less than 180°, since both the robot and the model are programmed to turn towards the direction with the smallest error. Using the export function within the program, the error data can be copied to the clipboard, and can be plotted alongside data from the robot. Figure 26 shows the error plot for a modeled turn. Also, at the top of the inputs section there is a “time elapsed” value that shows once a turn has been completed.

This is how long it took for the error to become less than 5 degrees, and provides a quick way to tell if one set of coefficients is better than another.

Often, multiple sets of coefficients will give the same output. This means that they all maximize the turn rate of the robot, which will optimize the turn. It is best to use the smallest coefficients possible that maximize the turn rate of the robot, in order to decrease the chance of overshoot, or the robot becoming unstable. Overshoot almost always leads to sustained oscillations in this system, because the system would constantly overshoot back and forth by the same amount. Derivative control will decrease the likelihood this will occur. The robot did this at times and would constantly search for the heading, going back and forth across it, but never finding it. The width of the oscillation is based to the minimum correction from Equation 12 and did not die out because even the minimum correction caused overshoot and the influence of the PID coefficients did not have any affect.

V. IMPLEMENTATION AND EVALUATION OF THE CONTROLLER

A. OPTIMIZATION AND TUNING

Each system has unique criteria for an optimized controller. The key criteria for this platform were to minimize the turn time and eliminate any large oscillations. Small oscillations can be tolerated within the limitations of the robot (± 5 degrees). In both the robot software and the model once the error is less than five degrees, the voltages are set to 2.5 V (stop voltage) for a pivot turn and 0.1 V (full forward) for a differential turn. This is a fairly large window, and could lead to a significant distance error from the destination if that course was followed the whole way. However, since the robot continually updates the course needed to reach the destination the error between the desired course and the current course eventually grows beyond 5 degrees, and a new turn will be initiated. The robot will travel shorter distances along any particular course as it nears the destination, but will stop when it comes within 4.6 meters, due to limits in GPS accuracy. Also, once the robot gets close to the final destination it is expected to be put in manual mode. The optimized coefficients for each turn are shown in Table 4 along with the time it takes to complete the turn. Integral control was not needed for a differential turn since the only systemic error observed was less than 5 degrees.

| | KP | KI | KD | Turn Time (Sec) (170 deg) | |
|--------------|----|----|-----|---------------------------|-------|
| | | | | Robot | Model |
| Differential | 1 | 0 | 3.5 | 5.4 | 5.1 |
| Pivot | 1 | 5 | 3 | 4.0 | 4.0 |

Table 4. Optimal Coefficients and Corresponding Turn Times

B. EVALUATION

To determine how well the model matched the real platform, the robot was programmed to make the same turns plotted with the model while recording heading data with each calculation. This was done with the same controller coefficients entered into the robot software as were input to the program. In Figures 27 through 30, below, the heading error versus time is shown for a 170 degree turn and a 90 degree turn for both

pivot turns (Figures 29 and 30) and differential turns (Figures 27 and 28). The particular turns were chosen because turns of approximately 90 degrees are commonly used in reaching the desired destination, and a turn of 170 degrees is close to the maximum.

The optimal coefficients from the model did give the fastest turns for the robot, and no noticeable oscillations were observed. Other coefficients were tested in the robot software to see if there were any that would make the robot complete the turn faster, and none were found.

Figure 27. Optimized differential turn, model and real data (170 degree turn)

Figure 28. Optimized differential turn, model and real data (90 degree turn)

A slightly different model was used to simulate a pivot turn, because the voltage set on the outside wheels is 5V minus the inside voltage, but for a differential turn the outside voltage is set to 1 V (full forward). Figures 29 and 30 show optimized turn data for pivot turns of 178 and 90 degrees.

Figure 29. Optimized pivot turn, model and real data (178 degree turn)

Figure 30. Optimized pivot turn, model and real data (90 degree turn)

The model does not exactly match what the robot does, because the fit used to approximate the turn is linear, whereas the turn is not really linear. The model was usually off by less than ten degrees at any given point. The time required to complete the turn that is reported by the program was off by 6%. Most importantly, the optimized coefficients in the program were also the optimized coefficients for the robot. Also, the maximum turn rate in the empirical model matched the maximum turn rate that was observed while testing the robot. There are many factors that change performance which were isolated to minimize error between the model and the platform. For example, even the charge on the battery affects how the robot turns. To minimize the influence of other factors, the robot was always tested on the same surface and on a full battery charge. The usefulness of the results is limited though, since the robot can operate on many different surfaces, even sloped ones, and will always have a changing battery charge. The different coefficients are used in the robot code based on the type of turn. When navigating to a new waypoint the robot uses the differential turn coefficients, but when the robot is in manual control and the operator enters a new direction to face in the graphical user interface (GUI) the pivot turn coefficients are used.

C. IMPROVED PERFORMANCE

The next step to improve how the robot changes direction would be to incorporate a steering mechanism on one or both sets of wheels, so the robot turns more like a car and less like a tank. While the hardware for this would be more complicated, it would have certain advantages. A control process may not even be necessary. A rotating servo would simply turn a set of wheels to the heading requested. The disadvantage would be that the robot could not pivot turn in place, unless a combination of steering systems were used. For some platforms or missions, the ability to turn in place may not be important.

In addition to different hardware, if a theoretical model was perfected, the robot could choose different control coefficients based on data it collects about its surroundings, or information sent from an operator during the initial mission load. No empirical model will model the system perfectly since conditions change constantly, but a good model should provide useful information about what the model does and how it responds, which this does.

THIS PAGE INTENTIONALLY LEFT BLANK

VI. CONCLUSION AND FUTURE WORK

A. APPLICATION TO OTHER PLATFORMS

The model developed for this platform could easily be applied to any other two or four wheeled robots that are reasonably similar to the one tested. New optimal coefficients could then be determined. The two things that would need to be changed in the model are the voltage limits and the equation that relates voltage difference to turning rate. The voltage limits are determined by the motor controller used on the new platform tested. The equations that relate voltage difference to turning rate can be found by measuring a change in heading for voltage difference from one side to the other in the usable voltage range. Then by applying a best fit equation that adequately represents how the robot turns, the platform response to a given voltage can be predicted.

Two simple tests would be enough to modify this model to another platform. One is a turn rate versus voltage difference for differential turn and the other is a turn rate versus voltage difference for a pivot turn. The initial turn limits can also be observed during these tests and adjusted. If a theoretical model were to be developed only the inertia and friction (platform and terrain dependent) of the platform would need to be entered, instead of the empirical equations.

This same process and the format of the software could also be applied to other industrial processes other than robots in situations where PID control is applicable. The whole process of modeling the response to an input and controlling that input is the same as the process used for this model and robot. A computer program can be very useful in tuning the controller and evaluating the model.

B. IMPROVING THIS WORK

It is possible to develop a theoretical equation of motion that governs the robot. The theoretical models that were developed as a part of this project did not match what the robot was doing well enough for any effective controller to be developed, most likely because the theoretical model involved imaginary numbers which are difficult to program in Visual Basic. It is also possible to incorporate control coefficients into the equation of

motion and solve for the optimized values. The equation of motion will need to include static friction for the rolling of the wheels, and in the case of a pivot turn will need to include kinetic friction since the wheels drag during this type of turn. The other main input into any theoretical model will have to be both the inertia of the platform and the inertia of the motors, which are acting in perpendicular planes. The equation would have voltage to the motors as the independent variable with a turning rate as the dependent variable.

Another aspect of this work is that the robot could potentially need different optimized coefficients if it is driving on different surfaces, such as grass, sand, cement, or gravel. The ultimate goal would be to have a theoretical model that can be used to determine control coefficients for different robots traveling over different surfaces, allowing the robot to choose a different set of coefficients depending on the type of surface it is traveling over.

C. SOFTWARE USER'S MANUAL

To run the included simulation programs the MSCHART.OCX file must be included in the folder the programs are run from. Double click the type of turn desired to be modeled. In the opening window five inputs exist:

1. Initial heading- this is the initial direction the robot is pointed.
2. Desired heading- the direction the robot needs to face after the turn. Usually, what is needed is a particular span of a turn- for example a 90 degree turn or a 180 degree turn. Any initial and final value can be used to give the necessary original error.
3. Proportional- the proportional control coefficient. This coefficient is unitless since the control only factors the original correction estimated by the robot.
4. Integral- the integral control coefficient. This will multiply the error over the last 10 time steps, and factors it into the next voltage assigned.
5. Derivative- the derivative control coefficient. This input multiplies the difference in the last two time steps by the coefficient entered and factors it into the next voltage signal.

Once the desired values are entered, click the “Go!” button. The program will simulate how the robot will respond to that set of values. The chart will automatically plot the heading versus time and error versus time data. In the top left of the screen a “Time Elapsed for Turn” box exists. A value will show up if the turn was completed successfully. This is the time it took for the error to come below 5 degrees and stay for five time steps. The time shown in the box is the time to the first of the five steps, but will not show up if the error does not stay within 5 degrees.

In order to plot the model data against data collected from the robot click the “Export” function. This will copy the data array that is plotted in the error versus time chart onto the clipboard. In another program, such as Excel, click paste and the data array will be show up. The data array includes the time step, time elapsed (in tenths of a second), and the error at the time.

To exit, click the “Quit” button. Any data in the program will be lost.
